11 **Abstract**

12 Hybrid membranes, featuring combinations of inorganic and organic materials at the nanometre or
13 molecular level, have been widely reported as providing superior separation performance compared
14 with the traditional polymeric membranes. However, for rational design of membranes, there remains
15 a major doubt as to how each constituent functions in the separation process. Herein, carbon nanotube
16 (CNT) incorporated poly (vinyl alcohol) (PVA) membranes were analysed using pervaporation (PV)
17 process for aqueous mixture separation. The impacts of CNT on the functional properties,
18 morphologies and microscale structures of the PVA/CNT hybrid membranes was investigated by ATR-
19 FTIR, AFM, SEM and positron annihilation lifetime spectroscopy (PALS). Further, a comparison of
20 the interactions between the membrane and solvents (water and ethanol) were identified by swelling
21 test and XRD. The resultant PVA/CNT hybrid membranes were then subject to both desalination and
22 dehydration of ethanol. The results showed that PVA exhibited preferential adsorption of water over
23 ethanol. The addition of CNT enlarged the fractional free volume (FFV) and enhanced water diffusivity

24 (up to 185%), which indicated a diffusion-dominated type of the PVA/CNT hybrid membranes with a
25 synergistic effect of CNT on water transport. The transport of Na⁺ ions through the membrane was
26 examined to be with larger activation energy than that of ethanol during the separation process. This
27 work investigated the state of polymer as well as the effect of nanofillers in the separation of water vs.
28 non-volatile or volatile component for the first time, which can provide in-depth understanding of the
29 polymer-based hybrid membranes for practical applications.

30 **Keywords:** Pervaporation; carbon nanotube; poly vinyl alcohol; desalination; dehydration of ethanol.

31 **1. Introduction**

32 Pervaporation (PV) is a membrane process in which the solutes transport through a semi-
33 permeable barrier via a route of preferential adsorption, permeation and desorption as described by the
34 generally accepted solution-diffusion theory [1-3]. Unlike conventional pressure-driven membrane
35 processes such as microfiltration (MF) [4], ultrafiltration (UF) [5], nanofiltration (NF) [6] and reverse
36 osmosis (RO) [7], PV involves a flow of gas or vacuum at the downstream side of the membrane,
37 which causes a partial pressure difference for continuous separation. A phase change from liquid to
38 vapor is observed across the membrane [8], with the membrane being active in determining selectivity
39 [9]. As such, PV shows notable advantages in separating similar-boiling point and azeotropic mixtures
40 over commonly utilized distillation [10]. Depending on the physicochemical properties, the PV
41 membranes can exhibit hydrophilic or organophilic (hydrophobic) property. The applications of PV
42 include dehydration of solvents, desalination and isolation of organics from aqueous-organic mixtures
43 or anhydrous organic mixtures. The past several decades have witnessed the rapid development of PV
44 in industry, particularly in the application of solvent dehydration using hydrophilic membranes. The

45 first industrial alcohol-water separation apparatus was established by GFT (Germany) in 1984 [9]. From
46 then on, large-scale applications have been developed rapidly by companies including PolyAn GmbH
47 (Germany), Pervatech B.V. (Netherlands), DeltaMem AG (management buy-out of Sulzer, Switzerland)
48 and Mitsubishi (Japan).

49 Although module construction and process optimization are indispensable for the development
50 of PV, separation ultimately relies on the membrane materials as they determine the mass transfer
51 characteristics [11]. So far, polymeric [12], inorganic [13] and hybrid materials [14] have been
52 extensively developed in attempts to advance the PV process. Hybrid membranes in particular are the
53 most appealing in pursuing high selectivity, permeability, processability and long term stability. [1].
54 With the inherited superior merits from both polymeric and inorganic membranes, hybrid membranes
55 are usually obtained by integrating the polymer matrix with inorganic fillers via physical blending [15],
56 sol-gel method [16], or layer by layer self-assembly [17], and are proven to address the inherent issues
57 of polymeric membranes (swelling, poor chemical and thermal stability) and inorganic membranes
58 (inferior film formation, highly brittle and unavoidable defects) [18-21]. Featuring multiphase
59 (typically polymer phase, inorganic phase and intermediate phase) and various interactions (van der
60 Waals force, hydrogen bond, π - π interaction, covalent and ionic bonds) spanning from nanoscale to
61 macroscale, the integration of these two disparate building blocks enables high flexibility toward
62 rational structure design of membrane, thus exhibiting new opportunities capable of tackling the trade-
63 off effect of higher flux at the expense of reduced selectivity [22]. For hydrophilic PV, poly (vinyl
64 alcohol) (PVA) is well suited as a membrane material due to its high affinity to water and excellent
65 film-forming properties. However, swelling and possible dissolution in aqueous environment hinders
66 its practical application [23, 24]. Modification of PVA by either chemical crosslinking or blending with

67 nanofillers is a prerequisite before use. PVA is often crosslinked with glutaraldehyde, maleic acid and
68 so forth because hydroxyl groups are reactive with aldehydes or carboxylic acid groups [25]. Although
69 crosslinking restrains swelling and ensures the stability of the membrane, it usually causes the
70 reduction of hydrophilic groups (the hydrophilicity of the membrane) and impedes the molecule
71 transport [26, 27]. Comparatively, PVA based organic-inorganic hybrids provide a judicious strategy
72 to further enhance the performance as they can possess the effective cross-linking between PVA chains
73 with crosslinkers while with the loaded nanofillers exhibiting specific functions.

74 To date, zeolite, silica (SiO_2), titanium dioxide (TiO_2), carbon nanotube (CNT), graphene oxide
75 (GO), graphene oxide quantum dot (GOQD) and metal-organic framework (MOF) have been
76 successfully incorporated into the PVA matrix with enhanced separation performance [28-33]. Based
77 on the morphology and geometry, they can be classified into two types: permeable nanofillers and
78 impermeable nanofillers as shown in Fig. 1. For nanoparticles (e.g., SiO_2 , TiO_2 and GO) incorporated
79 membranes, the dispersed phase is not permeable to the solutes (Fig. 1a) which results in a long and
80 tortuous path through the polymer continuous phase or the polymer-filler interface. On the other hand,
81 the dispersed porous fillers such as MOF and CNT, can provide an additional permeating pathway (Fig.
82 1b). In that case, transport through the dispersed phase can be usually described as molecular sieving,
83 surface adsorption, or bulk diffusion [34-36]. Similar to aquaporins with biological channels for fast
84 water transport in the biological-cell membranes, CNT as permeable nanofiller has similar structure
85 comprised of cylindrical carbon [37]. The spiralling of graphite sheets provides a smooth, narrow and
86 hydrophobic nanochannel for mass transport and it is reported that structure facilitates the formation
87 of confined water chains, as well as bearing weak interactions with water molecules for nearly barrier-
88 free transport [38]. Previous studies have reported remarkable enhancements in the water permeation

89 flux of the CNT incorporated membranes such as polyethersulfone (PES) , polyamide (PA) and
90 polyvinylidene fluoride (PVDF) [37, 39, 40]. Moreover, CNT has molecular sieving effect depending
91 on the diameter of the inner pore. A 0.93 nm diameter CNT or functionalized 1.09 nm diameter CNT
92 showed a salt rejection of over 95% [41]. However, for CNT incorporated membranes, even though
93 the diameter of CNT is much larger than the solutes, high separation performance of the membrane
94 can still be obtained. For example, Lee et al. [37] showed that the CNT of 10-20 nm diameter in
95 polyamide matrix exhibited a higher water flux than PA without CNT while there was almost no
96 sacrifice of salt rejection. Our previous study also demonstrated significant increases in permeation
97 flux of the crosslinked PVA/CNT hybrid membranes with high rejection for sodium chloride (NaCl)
98 [32]. However, nanoscale physicochemical changes of the polymer matrix such as free volume and
99 crystallinity which are highly associated with the permselectivity of the membrane, have been rarely
100 studied for hybrid membranes. Although CNT incorporated PVA membranes have been researched in
101 PV process [24, 42-44], the CNTs used were usually derived from acid oxidation under heating. That
102 made the influence of the CNT functional groups unclear due to the complex composition (-OH, -
103 COOH and -C=O) [45, 46]. The PVA matrix has variable types (crosslinked or uncrosslinked), which
104 calls for comparison to guide rational membrane design. More importantly, it is worthwhile
105 investigating the comprehensive separation capability of PVA based membranes toward both
106 desalination and alcohol dehydration for practical application.

118 **Fig. 1.** Permeation through (a) hybrid membrane with impermeable nanofillers and (b) hybrid membrane with
119 permeable nanofillers.

120 Herein, to address the abovementioned queries and gain further understanding, the transport
121 properties of the PVA/CNT hybrid membranes for both desalination and alcohol dehydration processes
122 were systematically investigated as a necessary extension for its proven separation capability with a
123 particular focus on the effect of various CNT (carboxyl functionalized or nonfunctionalized) on the
124 nano-physicochemical properties of polymer phase. Carboxyl functionalized and pristine CNTs are
125 served as nanofillers to compare the effect of functional groups. Crosslinked and uncrosslinked PVA
126 were employed as the polymer matrixes. As diffusion through the membrane is highly related to the
127 free volume and selective separation to the free volume cavity size, positron annihilation lifetime
128 spectroscopy (PALS) analysis was applied to the PVA based hybrid membranes. In addition, for
129 aqueous mixture separation, PV is subjected to strong interactions between water molecules and
130 hydrophilic membrane materials, and the properties of polymeric membranes in wet condition are
131 usually different compared with those in the dry state. Therefore, detailed wet state polymer phase
132 characterizations (XRD, wet state PALS and swelling) were investigated. This study aims to elucidate
133 how the polymer and nanofillers in hybrid membranes function in separating different type of aqueous

134 mixtures, and to correlate the inherent transport properties of the membrane with PV performance.

135 **2. Experimental**

136 *2.1. Materials*

137 PVA of 98-99% hydrolysed (molecular weight of 160,000 g/mol), maleic acid (MA), *p*-toluene
138 sulfonic acid (98.5% monohydrate), ethanol and NaCl obtained from Sigma-Aldrich were used as
139 received for the experiment. Two kinds of carbon nanotubes, i.e. multiwalled carbon nanotube
140 (MWCNT) as well as functionalised multiwalled carbon nanotube (F-MWCNT) with 3.86 wt% of
141 carboxyl groups were purchased from XFNANO Co. Ltd. The inner diameter of the above carbon
142 nanotubes was in the range 2-5 nm with the outer diameter < 8 nm and the specific surface area > 200
143 m²/g. The length of MWCNT and F-MWCNT was in the range of 0.5-2 µm. Milli-Q deionised water
144 (18.1 MΩ cm) was used throughout the study.

145 *2.2. Synthesis of PVA based hybrid membranes*

146 Firstly, 100 mg of MWCNT or F-MWCNT was dispersed in 50 mL of ethanol with ultrasonication
147 in an ice bath for 2 h. A mass of PVA powder (12 g) was dissolved slowly in 200 mL of Milli-Q
148 deionised water at 90°C and stirred for 3 h to obtain a homogeneous solution. After cooling to room
149 temperature, blending of the PVA/CNT mixture was realized by the addition of a predetermined
150 amount of MWCNT/ethanol or F-MWCNT/ethanol dispersion to the PVA solution. The composition
151 of the PVA/CNT membranes is presented in Table 1 and all the mass fractions of CNTs, MA and *p*-
152 toluene sulphonic acid were relative to the PVA. For the crosslinked PVA based membranes, specified
153 amounts of MA and *p*-toluene sulfonic acid (catalyst) were dissolved in the PVA solution or

154 PVA/FMWCNT mixture under stirring for 2 h. After degassing for 24 h, all the resultant mixtures, i.e.,
 155 the PVA-MA, PVA-CNT, PVA-FCNT, and PVA-MA-FCNT were cast on a plastic plate using a casting
 156 bar of 100 μm . After drying for 24 h, the obtained films were detached from the plate and treated under
 157 140 $^{\circ}\text{C}$ in an oven for 2 h as described elsewhere [32].

158 **Table 1**

159 The composition of the fabricated membranes.

Membranes	MWCNT loading (wt%)	F-MWCNT loading (wt%)	MA loading (wt%)	catalyst (wt%)	Membrane thickness (μm)
PVA-MA	-	-	20	1.5	19.5 \pm 1.7
PVA-CNT0.5	0.5	-	-	-	20.7 \pm 1.6
PVA-CNT1	1	-	-	-	20.5 \pm 2.1
PVA-CNT2	2	-	-	-	19.8 \pm 2.3
PVA-FCNT0.5	-	0.5	-	-	19.2 \pm 2.7
PVA-FCNT1	-	1	-	-	20.3 \pm 1.5
PVA-FCNT2	-	2	-	-	20.1 \pm 2.2
PVA-MA-FCNT0.5	-	0.5	20	1.5	21.2 \pm 2.4
PVA-MA-FCNT1	-	1	20	1.5	19.9 \pm 1.9
PVA-MA-FCNT2	-	2	20	1.5	20.9 \pm 1.6

160

161 *2.3. Characterisation of PVA based hybrid membranes*

162 For the characterisation of the fabricated membranes, 3 samples of each type of membranes (PVA-
 163 MA, PVA-CNT, PVA-FCNT and PVA-MA-FCNT) were tested. The surface and cross-section
 164 morphologies of the fabricated membrane were observed and photographed by Zeiss Merlin Gemini 2
 165 Field Emission Scanning Electron Microscopy (FESEM) and the TECNAI 12 transmission electron
 166 microscope (TEM). The surface roughness was probed by atomic force microscope (AFM) using SPM-
 167 9700 (SHIMADZU). The presence of functional groups was detected by attenuated total reflectance-
 168 Fourier transform infrared (ATR-FTIR) spectroscopy (Perkin-Elmer Spectrum 2000 FTIR instrument).

169 A Rigaku SmartLab X-ray Diffractometer, operating in parallel beam mode under CuK radiation (45kV,
 170 200mA), equipped with a HyPix-3000 detector, was employed to obtain the X-ray diffraction (XRD)
 171 patterns. For the wet state results, samples were immersed with water or ethanol for 96 h to ensure an
 172 equilibrium state. The samples were scanned over the 2θ range 10° to 50° rapidly before the
 173 evaporation of ethanol. The resultant degree of crystallinity was calculated according to [47]; where
 174 X_c is the degree of crystallinity, $I_c(2\theta)$ and $I_a(2\theta)$ are the X-ray scattering intensity of crystalline region
 175 and amorphous region, respectively.

$$176 \quad X_c = \frac{\int_{2\theta \neq 0} I_c(2\theta) d(2\theta)}{\int_{2\theta \neq 0} I_a(2\theta) d(2\theta) + \int_{2\theta \neq 0} I_c(2\theta) d(2\theta)} \times 100\% \quad (1.)$$

177 PALS was applied for the average free volume characterisation of both the dry and wet states
 178 according to our previous study [29, 48]. Briefly, the membranes were first annealed at 50°C overnight.
 179 Then, they were cut and piled to 4 mm in a nitrogen atmosphere with a Mylar sealed ^{22}Na positron
 180 source fixed in the middle of the sample followed by the measurement of an automated EG & GOrtec
 181 fast-fast spectrometer. After the dry state characterisation, the membranes were immersed in 3.5 wt%
 182 NaCl solution or ethanol overnight and measured in a sealed sample holder to prevent evaporation.
 183 The time resolution of the tests was 240 ps and the LT v9 software was used for analysing the resulted
 184 spectra [49]. The average pore radius (R), average volume of the free volume elements (V_F) and the
 185 fractional free volume (FFV) were obtained by the following equations assuming the free volume
 186 elements were distributed as spherical cavities in the polymer [50];

$$187 \quad \tau_3 = \frac{1}{2} \left[1 - \frac{R}{R+\Delta R} + \frac{1}{2\pi} \sin\left(\frac{2\pi R}{R+\Delta R}\right) \right]^{-1} \quad (2)$$

188
$$V_F = \frac{4}{3}R^3 \quad (3)$$

189
$$FFV = V_F I_3 \quad (4)$$

190 τ_3 is the o-Ps lifetime; ΔR of 1.66 Å is the empirical electron layer thickness [29] and I_3 is the
191 intensity of o-Ps.

192 The swelling properties were tested as follows: (1) pre-dried freestanding membrane samples
193 were soaked in DI water or ethanol at ambient temperature for 96 h to reach absorption equilibrium;
194 (2) the water or ethanol adsorbed on the surface were removed by tissues manually to obtain W_s as the
195 wet weight, and (3) the samples were then placed in an oven at 25 °C for 30 h and measured again for
196 the dry weight of W_d . The degree of swelling (DS) was calculated in Eq (5).

197
$$s = \frac{w_s - w_d}{w_d} \times 100\% \quad (5)$$

198 *2.4. Pervaporation performance evaluation*

199 PV separation tests were conducted using a bench-scale PV set-up as described elsewhere [14].
200 To be specific, a membrane with separating area of 12.6 cm² was employed. A predetermined NaCl
201 solution or ethanol/water mixture was circulated with a flow rate of 50 mL/min on the upstream side
202 of the membrane by a Masterflex® peristaltic pump. The feed temperature was kept as required via a
203 water bath. 1 Torr of vacuum pressure was maintained on the permeate side by a vacuum pump. Finally,
204 the permeating vapor were condensed in a dry-ice or liquid nitrogen cold trap. The performance tests
205 were performed on 3 samples of each type of membranes (PVA-MA, PVA-CNT, PVA-FCNT and PVA-
206 MA-FCNT) and conducted for 3 h upon reaching a stable state whereas the long-term tests were
207 operated for 30 h. Permeance (the normalized driving force for permeation flux in a unit of GPU = 1

208 $\times 10^{-6} \text{ m}^3(\text{STP})/\text{m}^2 \text{ s cmHg}$), selectivity (α), salt rejection, separation factor (β) for dehydration of
 209 ethanol were applied to evaluate the transport properties of the membranes based on Eq (6-10) [51,
 210 52]. Ethanol permeance can also be calculated using Eq (7). The salt concentration of the feed (C_f) and
 211 permeate (C_p) were derived from a pre-calibrated Oakton® Con 110 conductivity meter. For ethanol
 212 dehydration, the ethanol concentration in the permeate side was determined by nuclear magnetic
 213 resonance (NMR, Bruker 400 Ultrashield with Icon NMR analysis software).

$$214 \quad J_i = \frac{M_i}{A \times t} \quad (6)$$

$$215 \quad (P/l)_i = \frac{J_i}{P_{i0} - P_i} = \frac{J_i}{\gamma_{i0} x_{i0} P_{i0}^{sat} - P_{i0}} \quad (7)$$

$$216 \quad R = \frac{C_f - C_p}{C_f} \times 100\% \quad (8)$$

$$217 \quad \alpha = \frac{(P/l)_i}{(P/l)_j} \quad (9)$$

$$218 \quad \beta = \frac{Y_i/Y_j}{X_i/X_j} \quad (10)$$

219 For PV dehydration of ethanol, the weight fractions of each component i and j in the feed and
 220 permeate were denoted as X and Y , respectively. J_i ($\text{kg}/\text{m}^2 \text{ h}$) represented the permeation flux of
 221 component i in which M_i (mass of component i in the permeate side) was divided by the product of A
 222 (the effective membrane area) and t (permeation time).

223 For permeance calculation, J_i was converted to the volume under standard temperature and
 224 pressure (STP). P_{i0} and P_{il} represented the partial pressures of i in the feed and permeate side,

225 respectively. γ_{i0} (achieved by ASPEN HYSYS program) and x_{i0} were the activity coefficient and the
226 mole fraction of i in the feed solution, respectively. P_{i0}^{sat} was derived from the saturated vapor pressure
227 of pure component i whereas the pressure on the permeate side (P_{il}) was negligible. l (m) was the
228 thickness of the membrane.

229 2.5. Penetrant diffusion properties

230 The water diffusion coefficient D_w (m²/s) was investigated based on the time lag method [53]
231 using DI water as the feed. In Eq (11), Q , t , l and C_0 were the total amount of diffusing water per unit
232 surface of the membrane (kg/m²), time of pervaporation experiment (min), the thickness of the
233 membrane (m) and concentration (kg/m³) of water in membrane, respectively. The relationship
234 between Q and t , as well as the obtained D are shown in Fig. S4 in the supporting information. NaCl
235 diffusion through the synthesized membranes was investigated by the kinetic desorption method
236 described elsewhere [29]. The diffusivity was determined by Eq (12) where M_t and M_∞ were the
237 amount of NaCl in the solution at time t and the total amount when desorption was finished. The
238 solubility, K , was the ratio of the equilibrium amount of water or NaCl absorbed into the membrane
239 per unit membrane volume [54]. According to the solution-diffusion model, permeability, P , was the
240 product of D and K (both applicable for water and salt).

$$241 \quad Q = C_0 \left(\frac{D_w t}{l} + \frac{l}{3} \right) \quad (11)$$

$$242 \quad D_s = \frac{\pi \times l^2}{16} \left[\frac{d \left(\frac{M_t}{M_\infty} \right)}{d \left(t^{\frac{1}{2}} \right)} \right]^2 \quad (12)$$

243 $P = D \times K$ (13)

244 The relationship between the permeation flux and temperature for pervaporation generally follows
245 the Arrhenius equation (14) where A_i , R , T and E_a were the pre-exponential factor, the gas constant
246 (8.3145×10^{-3} kJ/mol K), the absolute temperature (K) and the apparent activation energy for the
247 permeation (kJ/mol), respectively [55].

248
$$J_i = A_i \exp\left(-\frac{E_a}{RT}\right)$$
 (14)

249

250 3. Results and discussion

251 3.1. Changes of the fabricated membranes with the addition of CNT.

252 3.1.1 Functional structure changes of the PVA/CNT hybrid membranes

253 In Fig. 2a, comparisons between pure PVA, PVA-MA, PVA-CNT1, PVA-FCNT1 and PVA-MA-
254 FCNT1 were performed using ATR-FTIR to identify the bulk chemistry changes that occurred in the
255 PVA/CNT hybrid membranes. In general, the characteristic bands at $3000-3500\text{ cm}^{-1}$, $2800-3000\text{ cm}^{-1}$,
256 $1400-1500\text{ cm}^{-1}$ and $1100-1000\text{ cm}^{-1}$, correspond to the -OH from intermolecular and intramolecular
257 hydrogen bonds, the stretching vibrations of C-H from alkyl groups, -CH₂ from PVA backbone and C-
258 OH stretching vibrations, respectively [26]. For the PVA-CNT1 and PVA-FCNT1 samples, the F-
259 MWCNT or MWCNT were physically mixed with PVA (PVA-FCNT spectra comparison with PVA-
260 MA in Fig. S1 in Supporting Information). On the other hand, C=O characteristic bands at a
261 wavenumber of $1710-1750\text{ cm}^{-1}$ and two C-O bands at $1330-1050\text{ cm}^{-1}$ (in the grey area of Fig. 2a.),

262 which were attributed to the formation of ester groups, were present for PVA-MA and PVA-MA-
 263 FCNT1. That implied the -OH from PVA reacted with -COOH from MA or F-MWCNT through
 264 dehydration condensation in the presence of catalyst under certain conditions such as the heat treatment.
 265 Since the F-MWCNT was functionalized with carboxyl groups, it was possible that they would be
 266 esterified with PVA apart from the presence of MA [56]. To further investigate the PVA-MA-FCNT
 267 system, Fig. 2b shows the transmittance spectra representing ester groups (grey area) that grew with
 268 F-MWCNT loading, indicating that more ester groups were generated upon addition of F-MWCNT.
 269 Meanwhile, transmittance in 3000-3500 cm^{-1} region decreased because of the consumption of
 270 hydrogen-bonded hydroxyl groups, coinciding with the augment of esterification reactions.

Fig. 2. ATR-FTIR spectra of the PVA based hybrid membranes.

279

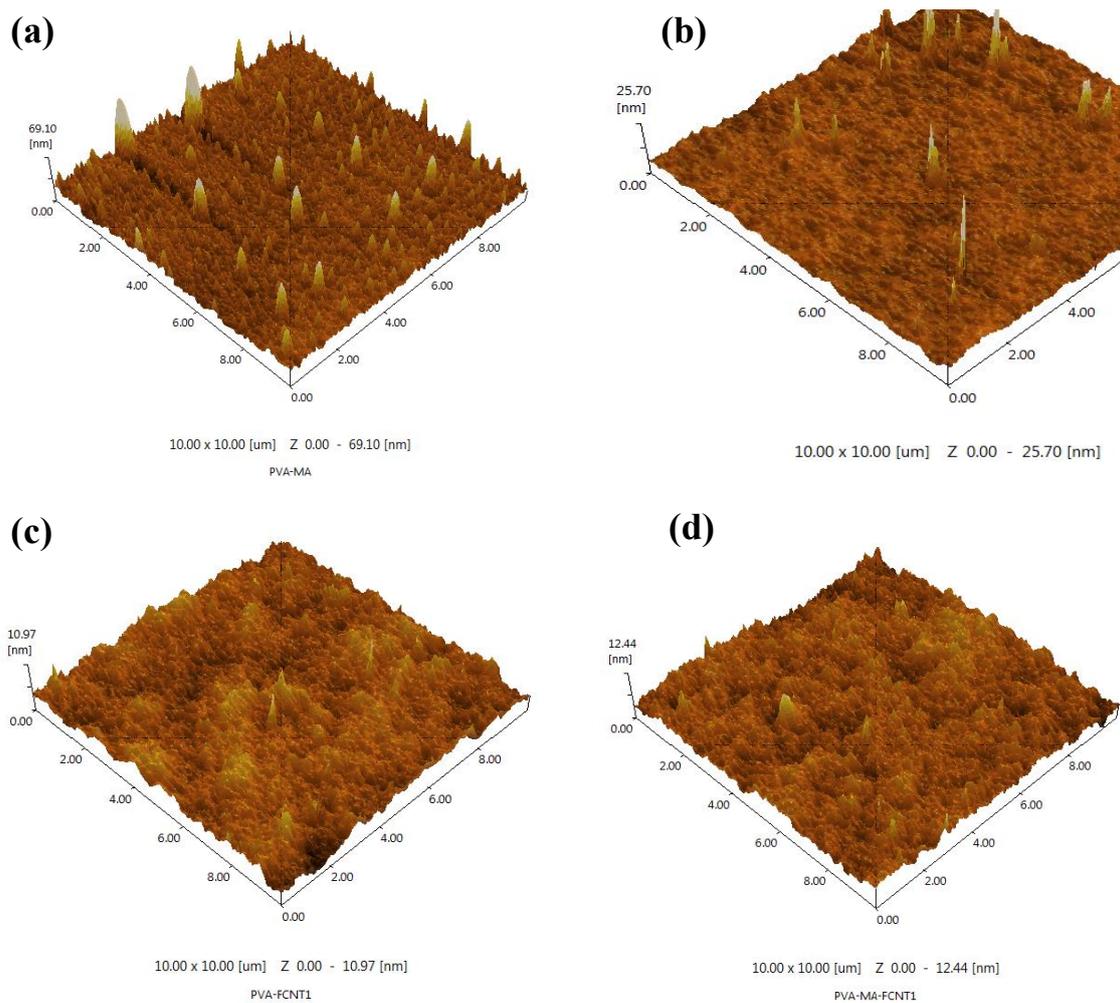

280 3.1.2 Morphology before and after the addition of CNT

281 The surface roughness changes of the PVA based hybrid membranes are presented in Fig.3. In
 282 comparison with PVA-MA ($R_a=69.1 \pm 6$ nm), the surface roughness of PVA-CNT1 decreased to $25.7 \pm$
 283 4 nm. The surfaces of the membranes were even smoother with the addition of functionalized CNT,
 284 i.e., 10.97 ± 2 nm for PVA-FCNT1 and 12.44 ± 3 nm for PVA-MA-FCNT1. Such surface morphology

285 transformation can be attributed to the PVA-nanofiller interactions and the subsequent film forming
286 kinetic. Blending of CNT allowed PVA to be less mobile during solvent evaporation and heat-treatment
287 whereas PVA chains without CNT were possible to become highly mobile especially when the heating
288 temperature was higher than its glass transition temperature. Compared with the MWCNT
289 incorporated membrane, the functional groups on F-MWCNT reinforced the interactions with PVA,
290 making it reasonable to exhibit flatter surface. Additionally, the corresponding photographs of the PVA
291 based membranes are shown in Fig. 4. The PVA-MA was transparent whilst the PVA/CNT membranes
292 were dark due to the addition of CNT. According to the photographs, it could be observed that the
293 dispersion of F-MWCNT in PVA was relatively uniform whereas macroscopic domains that were
294 possibly comprised of agglomerated MWCNTs could be found in PVA-CNT1.

295 The FESEM images of the PVA/CNT hybrid membranes with different CNT loadings are shown
296 in Fig. 5. As can be seen, the surface of the PVA-MA sample (Fig. 5a) was homogeneous without
297 defects such as cracks, ruptures or pinholes. While with the addition of F-MWCNT, the content of
298 inhomogeneous spots which may represent the CNT tips on the surface increased from PVA-MA-
299 FCNT0.5 to PVA-MA-FCNT1 (Fig. 5b to c). Interconnected bundle-like protrusions or wrinkles were
300 observed on the surface of PVA-MA-FCNT2 (Fig. 3d), implying the formation of the CNT
301 agglomeration. The corresponding cross-section pictures of PVA-MA-FCNT1 (Fig. 5e) and PVA-MA-
302 FCNT2 (Fig. 5f) showed good consistency with the surface morphology as the PVA/CNT hybrid
303 materials were distributed across the longitudinal direction. By contrast, for PVA-CNT1 (Fig. 5g),
304 which was with identical CNT loading as PVA-MA-FCNT1, large inclusions resulting from CNT-rich
305 domains or submicroscale entangled bundles became obvious on the membrane surface, suggesting
306 inferior dispersion of MWCNT in PVA compared with that of the F-MWCNT. Besides, the cross-

307 section of PVA-CNT1 (Fig. 5h) and PVA-CNT2 (Fig. 5i) exhibited increasing agglomeration in the
308 polymer matrix with internal crumpled morphology. It is widely acknowledged that nanomaterials with
309 high surface energy easily agglomerate owing to van der Waals forces [57]. The functionalization of
310 CNT with carboxylic groups changed the hydrophobicity of the outer surface, improving the
311 hydrophilicity and the interfacial interactions with PVA. That is conducive to disentanglement of CNT
312 in the polymer matrix, thus showing good compatibility and uniform dispersion. On the other hand,
313 the increase in the CNT loading induced significant morphological change of PVA-CNT1 and PVA-
314 CNT2, which might result from the development of the entropically-driven phase separation behaviour
315 with the agglomeration of the nanomaterials in the polymer as investigated by Akcora [58].

369 *3.2. Interactions with water and ethanol*

370 *3.2.1 Swelling behaviour in different solvents*

371 Table 2 shows the degree of swelling (DS) of the membranes in various solvents at room
372 temperature. Clearly, the DS in water was far greater than that in ethanol for all the membrane samples,
373 showing the solvent-dependent swelling behaviour of the PVA based membranes. It is understandable
374 that chemical crosslinking reduced the number of hydroxyl groups of PVA and that resulted in a
375 decrement of the DS. The DS was further restrained when the F-MWCNT loading for PVA-MA-FCNT
376 was 2 wt%. That was a direct indication of the extra chemical linkage of F-MWCNT and PVA within
377 the membrane. For the blended membranes, swelling in water decreased with the content of CNT,
378 which was mainly attributed to the increased rigidification [56]. The rigidification in turn decreases
379 the mobility of polymer chains as a physical anti-swelling effect. In addition, for the PVA-FCNT
380 membranes, there was strong interaction between the hydrophilic functional groups [59], which further
381 suppressed polymer chain mobility. On the other hand, as PVA is an ethanol-insoluble polymer, the
382 hybrid membranes showed almost complete swelling resistance and it was even further inhibited with
383 CNT content in the polymer for PVA-FCNT and PVA-MA-FCNT membranes. However, it can be
384 observed that the ethanol swelling of PVA-CNT membranes was proportional to MWCNT loading.
385 Due to the hydrophobic nature of MWCNTs, they could be readily dispersed in ethanol and the resulted
386 PVA-CNT membranes were imparted with better compatibility with ethanol, thus showing higher
387 swelling degree compared with others.

394 3.2.2 Effect of solvents on the crystalline properties of the PVA based membranes

395 Fig. 6 displays the XRD diffraction profiles of both dry and wetted states of the hybrid membranes.
 396 For the dry-state membranes in Fig. 6a, strong peaks at $2\theta = 19.5^\circ$, referring to the characteristic peaks
 397 for the orthorhombic lattice (101) of PVA were present for all the samples which indicated the
 398 crystalline region in the semi-crystalline PVA polymer. There was a decrease in this peak intensity for
 399 the crosslinked membranes compared with those of the blended membranes. The reason for that was
 400 the consumption of hydroxyl groups by the crosslinking reaction. For the samples wetted with ethanol
 401 in Fig. 6b, the diffraction profiles were almost identical with those of the dry-state samples except for
 402 tiny decreases in the peak intensities. That might be the interference of the trapped ethanol in the
 403 polymer matrix. The amorphous portion remained a glassy state in ethanol. However, the XRD patterns
 404 of the water-swollen membranes were transformed to two dominant halo-shaped peaks centred around
 405 2θ of 28° and 43° . The diffraction patterns exhibited more of the characteristic peaks of water as
 406 reported in previous literature [60]. In that case, there were new intermediate phases including the PVA
 407 chains and water molecules, or the CNT and water. It could be demonstrated that a large amount of the

408 crystalline PVA had been dissolved by long-term contact of water, forming a large swollen amorphous
 409 PVA phase. The corresponding degree of crystallinity was calculated as shown in Table 3. Compared
 410 with the reduction of crystallinity in ethanol (3.8% for PVA-MA, 7.1% for PVA-CNT1, 4.6% for PVA-
 411 FCNT1 and 4.1% for PVA-MA-FCNT1), a significant decrease in PVA crystallinity in water was
 412 confirmed with 62.8%, 90.2%, 83.1% and 63.3% for PVA-MA, PVA-CNT1, PVA-FCNT1 and PVA-
 413 MA-FCNT1, respectively. Overall, the semi-crystalline nature of dry PVA did not show an obvious
 414 difference with ethanol, whereas it was altered by water with significant decrease in the degree of
 415 crystallinity as shown by the reduction in crystalline phase [61].

429

3.2.3 PALS analysis of the PVA based hybrid membranes

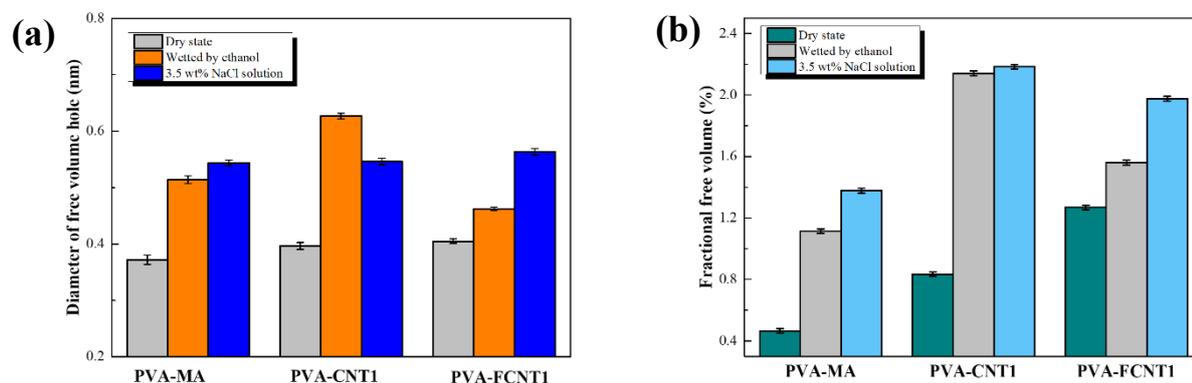

Fig. 7. PALS results of (a) average free volume cavity diameter and (b) FFV.

The changes of the free volume properties for the PVA based hybrid membranes in dry and swollen states were characterized by PALS in terms of free volume cavity diameter (Fig. 7a) and FFV (Fig. 7b). The PVA-MA-FCNT membranes showed signs of positronium inhibition, however, no o-Ps formed which made it difficult for obtaining reliable pore size and intensity data. Therefore, only the PALS results of PVA-MA, PVA-FCNT and PVA-CNT membranes can be discussed in this section. In Fig. 7a, compared with PVA-MA (0.372 ± 0.008 nm), there were notable increases in the diameters for the PVA/CNT hybrid membranes, i.e., 0.396 ± 0.006 nm for PVA-CNT1, 0.405 ± 0.004 nm for PVA-FCNT1. As reported previously [62], a dramatic increase in the interfacial area was usually realized by intercalating nanoscale inorganic fillers of high specific surface area into the polymer matrix, leading to a large amount of volume fraction of interfacial polymer with distinguished properties from the bulk polymer. As a result, the free volume of polymer grew with the addition of nanofillers rather than a compacted structure of the neat polymer. Moreover, the dispersion state of F-MWCNT was much better than MWCNT, resulting in a greater available interface area. That might contribute to a higher free volume diameter for PVA-FCNT1. For the swollen membranes, it could be seen that the diameters were enlarged to 0.514 ± 0.007 nm for PVA-MA, 0.627 ± 0.005 nm for PVA-

452 CNT1, 0.462 ± 0.003 nm for PVA-FCNT1 (ethanol wetted membranes), and 0.544 ± 0.005 nm for
453 PVA-MA, 0.546 ± 0.002 nm for PVA-CNT1, 0.563 ± 0.002 nm for PVA-FCNT1 (water wetted
454 membranes), showing a solvent effect on changing the polymer backbone chain mobility and thus the
455 free volume. However, the hole diameter of PVA-CNT1 in ethanol was significantly different to the
456 others as a result of the affinity and adsorptive property of MWCNT to ethanol.

457 The FFV (Fig. 7b), namely the free volume scaled on the specific volume of the membrane matrix,
458 showed good coherence with the trend of pore size diameters. After the incorporation of carbon
459 nanotube, the FFV of PVA-MA was increased by 79% (PVA-CNT1) and 172% (PVA-FCNT1) for the
460 dry state; 59% (PVA-CNT1) and 43% (PVA-FCNT1) for the water wetted state and 92% (PVA-CNT1)
461 and 40% (PVA-FCNT1) for the ethanol wetted state. It is notable that the FFV of PVA-FCNT1 was
462 much higher than that of PVA-CNT1 in the dry state. That could be reasonably attributed to the better
463 dispersion state of F-MWCNT, effectively disrupting the polymer chain packing. On the other hand,
464 the MWCNT showed good compatibility with ethanol, thus the FFV in ethanol wetted state was
465 obviously higher than that of PVA-FCNT, in line with the pore diameter results. As the diffusion
466 through the membrane is intrinsically related to the microstructure of the membrane, the enrichment
467 of free volume would exert an influence on the transport property and separation performance based
468 on the free volume theory [62].

469 3.3. PVA/CNT membrane separation performance

470 3.3.1. Comparison between PV desalination and dehydration of ethanol

471 The PV performance of the synthesized membranes for both desalination and dehydration of
472 ethanol at a feed temperature of 30 °C was evaluated in terms of water permeance, salt rejection and
473 separation factor as depicted in Fig. 8. For desalination (Fig. 8a), the crosslinked PVA network (PVA-

474 MA) showed salt rejection of 96.5% with water permeance of 6.13×10^4 GPU. After the incorporation
475 of CNT, a significant improvement of the water permeance could be observed. For PVA-CNT1, the
476 water permeance was increased by 116% with respect to that of PVA-MA but a decreased salt rejection
477 of 93.4%. The lower salt rejection of PVA-CNT can be attributed to the severe swelling and inferior
478 dispersion state of MWCNT that increased the nonselective transport (discussion of salt permeability
479 in 3.3.2). The PVA-FCNT1 exhibited a better salt rejection of 97.4% as well as water permeance up to
480 11.9×10^4 GPU. The best overall desalination performance was observed when the PVA was
481 crosslinked with MA and F-MWCNT, i.e., 99.9% of salt rejection with 7.4×10^4 GPU of water
482 permeance. Likewise, the dehydration of ethanol was conducted as shown in Fig. 8b. The water content
483 in the permeate side was 95.5 wt% (PVA-MA), 90.1 wt% (PVA-CNT1), 98.1 wt% (PVA-FCNT1) and
484 99.5 wt% (PVA-MA-FCNT1), resulting in separation factors of 505.3, 216.7, 1229.3 and 4738.1,
485 respectively. The water permeance followed a similar trend as those in the desalination process yet
486 with much lower values. It is reasonable that the permeance in the desalination process was higher
487 than that of ethanol dehydration process because the aqueous salt solution as the feed contained many
488 more free water molecules following a pseudo-liquid mixture mode. On the other hand, considering
489 that the ethanol content in the feed was much higher than NaCl (96 wt% : 3.5 wt%), better separation
490 performance was obtained during the ethanol dehydration process, implying an intrinsic difference
491 between these two PV processes. For desalination, NaCl was unable to permeate through the
492 membrane in its crystalloid state and thus the transport was realized by the hydration of the Na^+ and
493 Cl^- ions and then the dissolution into the membrane. In order to keep charge neutrality, both hydrated
494 Na^+ ions and Cl^- ions permeated through the membrane stoichiometrically. For separation of ethanol-
495 water mixture, ethanol formed hydrogen bonding with water while kept its molecularity. PVA showed

496 a preferential adsorption selectivity for water as discussed in the swelling test.

497 For further investigation, the effect of feed concentration was investigated as illustrated in Fig. 9.
498 Overall, the water permeance was positively correlated to the water content in the feed as a result of
499 the sorption of water at the liquid/membrane interface. For PVA-MA, PVA-CNT1 and PVA-FCNT1,
500 the salt rejections decreased when NaCl concentration in the feed grew gradually, while the ethanol in
501 the permeate (otherwise the water content in the permeate) increased with water concentration in the
502 feed. Therefore, it could be identified that the water content played different roles in affecting the
503 separation process. For desalination, diffusion of NaCl in the membrane exhibited a concentration-
504 dependant effect due to the increased dissolution of NaCl in the membrane. However, for ethanol
505 dehydration, the increase in water content caused the swelling of the PVA and thus a plasticization
506 effect, which enhanced segmental polymer chain mobility [63] and decreased the selectivity between
507 water and ethanol. Notably, the PVA-MA-FCNT1 had a stable performance in both PV processes with
508 nearly complete rejections, proving that the crosslinked PVA with good swelling resistance hindered
509 the transport of salts and alcohol effectively while allowing effective permeation of water molecules.
510 Such good performance of PVA-MA-FCNT1 was further proven by comparison with PVA-FCNT1 in
511 a 30 h ethanol dehydration test, in which PVA-MA-FCNT1 exhibited stable performance whereas the
512 separation efficiency of PVA-FCNT1 declined with time (Fig. S3 in Supporting Information).

536

537

538

539

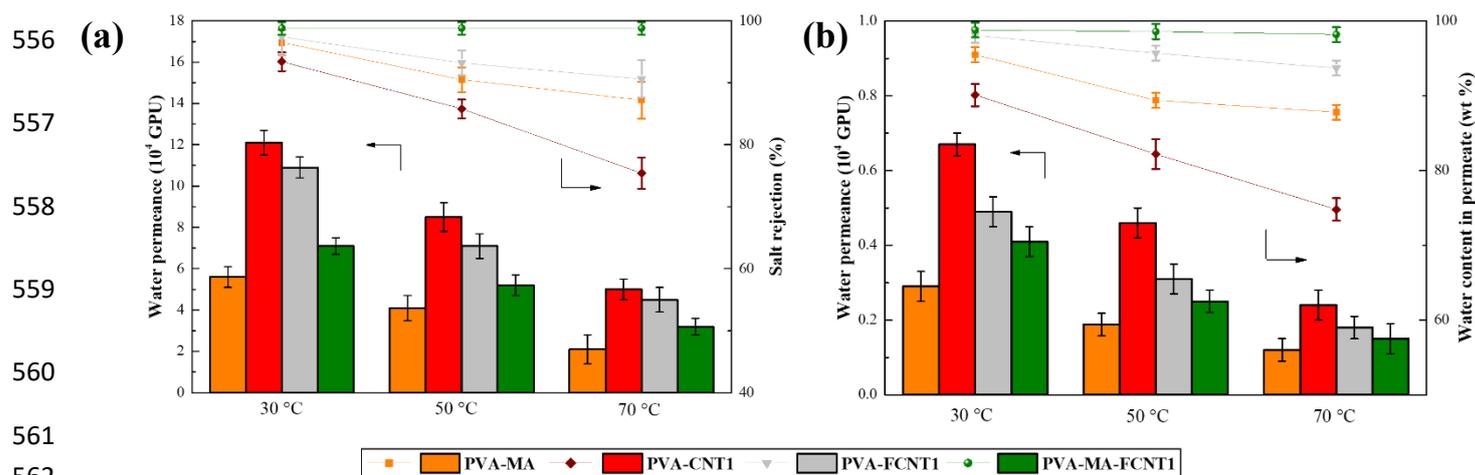

540

541

The effect of feed temperature on the PV process was performed from 30 °C to 70 °C. The separation performance is displayed in Fig. 10, where gradual declines of water permeance with temperature were observed. This is mainly due to the rapid increase in the partial vapor pressure of water (31.84 Torr for 30 °C, 92.58 Torr for 50 °C and 233.84 Torr for 70 °C) in the feed side after normalizing the driving force. The temperature dependency of the transport can be analysed using an Arrhenius-type equation. Activation energy (E_a) for water, hydrated Na^+ ions (same with Cl^- ions) and

542 ethanol transport were listed in Table 4 (logarithmic plots using Eq 14 in Fig.S2 in Supporting
 543 Information). As discussed above, NaCl dissociated and water molecules formed concentric hydration
 544 shells around the ions. Ethanol was also dissolved by forming hydrogen bonds with water. From the
 545 PALS results in 3.2.3, the average pore sizes of the PVA based hybrid membranes were smaller than
 546 the hydrated sizes of ions and ethanol (0.66 nm for Cl^- , 0.72 nm for Na^+ and 0.68 nm for ethanol).
 547 Hence, permeation of salt through the free volume might be realized upon removing some water
 548 molecules from the hydration shell to form smaller hydrated ions or ethanol. The E_a demonstrated the
 549 energy barrier for permeation and the solutes with higher E_a were expected to experience larger energy
 550 barriers for entry into the free volume and exponentially smaller permeation rates. The activation
 551 energy for permeation of NaCl was higher than ethanol or water, indicating that NaCl required more
 552 energy to permeate through. In addition, as a volatile compound, ethanol has an increasing partial
 553 vapor pressure difference across the membrane when temperature is increased. That contributes to the
 554 enhanced ethanol transport through the membrane.

555

ethanol	46.31	44.73	44.48	43.40
Na ⁺	49.47	49.80	49.88	49.30

569

570 *3.3.2. Effects of CNT on water transport and separation*

571 To further investigate the contribution of CNT to the water permeation mechanism of the PVA
572 based hybrid membranes, water solubility and diffusivity were calculated. Fig. 11 shows the variation
573 of solubility (dimensionless) and diffusivity (cm²/s) before and after the addition of CNT scaled on
574 that of PVA-MA (Q-t relation in Fig.S4 in the Supporting Information). As shown, PVA-CNT1 and
575 PVA-FCNT1 had increased water solubilities while PVA-MA-FCNT1 showed a decreased one.
576 Notably, the diffusivities were all elevated (85% for PVA-CNT1, 77% for PVA-FCNT1 and 56% for
577 PVA-MA-FCNT1). As both the solubility and diffusivity contributed to the water transport through
578 the membranes according to the solution-diffusion theory, the evolution implied that the water
579 transport was altered to a diffusion-controlled type with reinforced interfacial interactions between
580 CNT and PVA. It was demonstrated earlier that the incorporation of CNT increased the FFV (Fig. 7)
581 and therefore favoured water transport. However, taking the PVA-FCNT1 for example, the increase in
582 the FFV was only increasing 43% compared with the PVA-MA, while that of diffusivity is 77%. This
583 may imply that the F-MWCNT contributed to the fast water transport synergistically as extra water
584 transport channel. More specifically, the TEM image of PVA-FCNT1 is employed to illustrate
585 transport with nanochannels as shown in Fig. 12. The F-MWCNT was distributed uniformly in the
586 polymer. The proposed transport was that water permeated through the polymer matrix with dispersed

587 nanochannels. When they encountered F-MWCNT, the transport was enhanced by flowing through the
588 hollow space or along the outer surface. The overall water permeation was facilitated as the F-
589 MWCNT contributed to water transport partly along the whole water permeation path through the
590 membrane. It is worth mentioning that the dispersion state of CNT in the polymer plays an important
591 role in determining the separation performance. As MWCNT is hydrophobic, there is an strong
592 tendency to be immobilized in bundles, thus increasing the probability of defects. Finally, the effect of
593 CNT loading on the separation performance is shown in Fig.13. For the blended hybrid membranes
594 (PVA-CNT and PVA-FCNT), the water permeation increased with MWCNT and F-MWCNT (from
595 0.5 wt% to 2 wt%) as the number of nanochannels in the polymer matrix were rising. For PVA-MA-
596 FCNT, the water permeance decreased at 1% CNT loading, which implied that the transport was
597 hindered by increased crosslinking. While when the CNT loading reached 2%, the water permeance
598 was the highest for all the membranes. That might be the result of F-MWCNT agglomeration in the
599 membrane when the concentration of nanofiller was relatively high as shown in SEM (Fig.5).
600 Corresponding salt permeability and ethanol permeance were also depicted in Fig.14. The PVA-CNT
601 membranes had much higher salt permeabilities than PVA-FCNT and PVA-MA-FCNT membranes,
602 which can be attributed to their higher swelling. That negatively augmented the solubility of NaCl in
603 the membrane [32]. Further, the poor dispersion and lack of functional groups of CNT were conducive
604 to nonselective transport through the membrane [37]. Therefore, the high salt permeability proved
605 inferior for salt rejection of the PVA-CNT membranes. Similar trend was also observed for the ethanol
606 permeance. It should be noted that there were significant increases in both the salt and ethanol transport
607 at 2 wt% loading of MWCNT and F-MWCNT, implying the nonselective microscopic defects had
608 already existed in the membrane, elevating the nonselective transport in line with the above water

609 permeance results.

671 4. Conclusions

672 In this work, PVA/CNT hybrid membranes with different combinations were employed to
673 investigate the functions of the polymer and CNT in the PV separation processes of water/NaCl and
674 water/ethanol. For the PVA matrix, the incorporation of CNT induced an increase in both the free
675 volume cavity diameter and the fractional free volume, which is favourable for the water transport
676 through the membranes. The states of the polymer in various solvents were found to be responsible for
677 the separation of ions/water and ethanol/water. The PVA showed inherent adsorption affinity of water
678 over ethanol, which significantly affected the polymer chain mobility and the crystalline structure.

679 Compared with the blended membranes (PVA-CNT1 and PVA-FCNT1), the PVA-MA-FCNT1
680 membrane was proven to have high separation performance with nearly complete rejection of ions and
681 ethanol. The water diffusion results further implied enhanced water transport potentially brought by
682 the CNT with additional fast water transport paths. Overall, this work provided a comprehensive study
683 on how the polymer and nanofillers contributed to the separation of aqueous mixtures, benefiting the
684 judicious design of polymer-based hybrid membranes and applications.
