## Key points

- AMP-activated protein kinase (AMPK) is considered a major regulator of skeletal muscle metabolism during exercise.
- However, we previously showed that, although AMPK activity increases by 8–10-fold during  $\sim 120$  min of exercise at  $\sim 65\%$   $\dot{V}_{O_2\text{peak}}$  in untrained individuals, there is no increase in these individuals after only 10 days of exercise training (longitudinal study).
- In a cross-sectional study, we show that there is also a lack of activation of skeletal muscle AMPK during 120 min of cycling exercise at  $65\%$   $\dot{V}_{O_2\text{peak}}$  in endurance-trained individuals.
- These findings indicate that AMPK is not an important regulator of exercise metabolism during 120 min of exercise at  $65\%$   $\dot{V}_{O_2\text{peak}}$  in endurance trained men.
- It is important that more energy is directed towards examining other potential regulators of exercise metabolism.

**Abstract** AMP-activated protein kinase (AMPK) is considered a major regulator of skeletal muscle metabolism during exercise. Indeed, AMPK is activated during exercise and activation of AMPK by 5-aminoimidazole-4-carboxamide-ribonucleoside (AICAR) increases skeletal muscle glucose uptake and fat oxidation. However, we have previously shown that, although AMPK activity increases by 8–10-fold during  $\sim 120$  min of exercise at  $\sim 65\%$   $\dot{V}_{O_2\text{peak}}$  in untrained individuals, there is no increase in these individuals after only 10 days of exercise training (longitudinal study). In a cross-sectional study, we examined whether there is also a lack of activation of skeletal muscle AMPK during 120 min of cycling exercise at  $65\%$   $\dot{V}_{O_2\text{peak}}$  in endurance-trained individuals. Eleven untrained (UT;  $\dot{V}_{O_2\text{peak}} = 37.9 \pm 5.6 \text{ ml.kg}^{-1} \text{ min}^{-1}$ )

**Glenn K. McConell** is a Professor of Exercise Metabolism at Victoria University. He has 30 years of experience in exercise metabolism research and is internationally recognized with regard to the regulation of skeletal muscle glucose uptake in normal physiology and in diabetes. His research focuses on glucose metabolism and exercise, including examining the factors regulating skeletal muscle glucose uptake during exercise and the increase in insulin sensitivity after exercise. He has also been examining whether exercise early in life can prevent the insulin resistance associated with being born small for gestational age or having an obese father, and has he begun examining whether exercise can overcome the insulin resistance caused by shift work.

and seven endurance trained (ET;  $\dot{V}_{O_{2peak}} = 61.8 \pm 2.2 \text{ ml.kg}^{-1} \text{ min}^{-1}$ ) males completed 120 min of cycling exercise at  $66 \pm 4\%$   $\dot{V}_{O_{2peak}}$  (UT:  $100 \pm 21 \text{ W}$ ; ET:  $190 \pm 15 \text{ W}$ ). Muscle biopsies were obtained at rest and following 30 and 120 min of exercise. Muscle glycogen was significantly ( $P < 0.05$ ) higher before exercise in ET and decreased similarly during exercise in the ET and UT individuals. Exercise significantly increased calculated skeletal muscle free AMP content and more so in the UT individuals. Exercise significantly ( $P < 0.05$ ) increased skeletal muscle AMPK  $\alpha 2$  activity (4-fold), AMPK  $\alpha\text{Thr}^{172}$  phosphorylation (2-fold) and ACC $\beta$  Ser<sup>222</sup> phosphorylation (2-fold) in the UT individuals but not in the ET individuals. These findings indicate that AMPK is not an important regulator of exercise metabolism during 120 min of exercise at 65%  $\dot{V}_{O_{2peak}}$  in endurance trained men.

## Introduction

The signalling events that regulate skeletal muscle exercise metabolism have not been fully elucidated (Richter & Hargreaves, 2013). There is evidence for feed forward (calcium activated CaMK) (Wright *et al.* 2004; Wright *et al.* 2005; Jensen *et al.* 2007; Witczak *et al.* 2010) and feedback (AMP-activated protein kinase; AMPK) (Hayashi *et al.* 1998; Mu *et al.* 2001; Lee-Young *et al.* 2009; Abbott *et al.* 2011) regulation being involved, as well as nitric oxide (Balon & Nadler, 1997; Roberts *et al.* 1997; Bradley *et al.* 1999; Inyard *et al.* 2007; Ross *et al.* 2007; Merry *et al.* 2010a) and reactive oxygen species production (Toyoda *et al.* 2004; Sandstrom *et al.* 2006; Merry *et al.* 2010a), which are increased during contraction (Roberts *et al.* 1999; Reid & Durham, 2002; Linden *et al.* 2011). There is also some evidence that cytoskeletal forces during contraction may signal glucose uptake via Rac1 (SyLOW *et al.* 2013; SyLOW *et al.* 2015).

Skeletal muscle AMPK activity increases during exercise in rodents (Winder & Hardie, 1996; Lee-Young *et al.* 2009) and humans (Chen *et al.* 2000; Fujii *et al.* 2000; Wojtaszewski *et al.* 2000; Musi *et al.* 2001; Mortensen *et al.* 2013) and, given that activation of AMPK by 5-aminoimidazole-4-carboxamide-ribonucleoside (AICAR) increases skeletal muscle glucose uptake and fat oxidation (Merrill *et al.* 1997; Hayashi *et al.* 2000; Jorgensen *et al.* 2004), it has been assumed that activation of AMPK during exercise increase fat and glucose metabolism in humans. However, a number of studies have shown dissociations between activation of AMPK and glucose uptake during muscle contraction in rodents (Jorgensen *et al.* 2004; Fujii *et al.* 2005; Kjobsted *et al.* 2017) and during exercise in humans (Wojtaszewski *et al.* 2000; McConell *et al.* 2005; Mortensen *et al.* 2013). In addition, several studies have shown that fat oxidation increases normally during contraction (Jeppesen *et al.* 2011) and during exercise (Jeppesen *et al.* 2013) in AMPK dominant negative/kinase dead mice.

Further evidence that questions a role for AMPK in glucose and fat metabolism during exercise is that substantial increases in glucose uptake and fat oxidation are seen during low intensity exercise (40–45%  $\dot{V}_{O_{2peak}}$ ) in humans even though AMPK signalling is not increased at such intensities (Wojtaszewski *et al.* 2002; Chen *et al.* 2003). In addition, in a longitudinal study, we showed in previously untrained men that 10 days of exercise training abolishes the  $\sim 10$ -fold increase in AMPK  $\alpha 2$  activity during exercise at 65%  $\dot{V}_{O_{2peak}}$  despite fat oxidation being higher and glucose disposal, although attenuated, still being substantially increased during exercise (McConell *et al.* 2005). We found no relationship between AMPK activation (and AMPK  $\alpha\text{Thr}^{172}$  phosphorylation and ACC $\beta$  phosphorylation) and muscle glycogen use, glucose uptake and fat oxidation during exercise (McConell *et al.* 2005). There is no doubt that AMPK activation during exercise is important for post-exercise adaptations (Winder *et al.* 2000; McGee *et al.* 2003), although these findings imply that AMPK activation during moderate intensity exercise is not necessary for normal increases in glucose uptake and fat oxidation during exercise.

It can be argued that there is less activation of AMPK after short-term exercise training because there is less of an energy deficit in skeletal muscle during exercise. Indeed, we found this to be the case in humans in our short-term training study reporting no activation of AMPK during exercise at 65% of pretraining  $\dot{V}_{O_{2peak}}$  (McConell *et al.* 2005). The exercise after training was conducted at the pre-exercise training workload; as such, the exercise was at a little lower relative workload after training (McConell *et al.* 2005). However, it has subsequently been shown in humans that, after 12 weeks of exercise training, there is less activation of skeletal muscle AMPK when the post training exercise was conducted at the same relative intensity of 65%  $\dot{V}_{O_{2peak}}$  as the pre-training exercise (Mortensen *et al.* 2013).

Another way of examining the effect of exercise training on AMPK activation is to conduct a cross-sectional study

comparing endurance trained with untrained individuals exercising at the same relative intensity. Nielsen *et al.* (2003) found similar increases in AMPK  $\alpha_2$  activity during 20 min of exercise at 80%  $\dot{V}_{O_2\text{peak}}$  in trained compared with untrained individuals. This was surprising because they and others have found less of a skeletal muscle energy imbalance and therefore less of an increase in skeletal muscle AMP and ADP at 80%  $\dot{V}_{O_2\text{peak}}$  in trained compared with untrained men (Baldwin *et al.* 1999; Nielsen *et al.* 2003). It is not known whether skeletal muscle AMPK activity would increase during prolonged moderate intensity exercise in well trained individuals. This is important to determine because, if AMPK does not increase during such exercise, this would imply that AMPK is not important for the regulation of exercise metabolism during such exercise.

Therefore, the present study aimed to examine whether long-term endurance exercise trained individuals have an increase in skeletal muscle AMPK during 120 min of exercise at 65%  $\dot{V}_{O_2\text{peak}}$ . Based on our findings of no activation at this workload in previously untrained individuals after 10 days of exercise training (McConnell *et al.* 2005), we hypothesized that skeletal muscle AMPK would not be activated during 120 min of exercise at 65%  $\dot{V}_{O_2\text{peak}}$  in endurance trained men.

## Methods

### Ethical approval

The present study was approved by the Human Research Ethics Committee of the University of Melbourne (Study number 040090) and conducted in accordance with the *Declaration of Helsinki*, except for registration in a database.

### Subjects

Seven endurance-trained cyclists and triathletes ( $26 \pm 2$  years;  $72 \pm 4$  kg;  $\dot{V}_{O_2\text{peak}} = 4.4 \pm 0.35$  L min<sup>-1</sup>, mean  $\pm$  SD) and eleven healthy but otherwise untrained ( $23 \pm 3$  years;  $69 \pm 9$  kg;  $\dot{V}_{O_2\text{peak}} = 2.6 \pm 0.4$  L min<sup>-1</sup>, mean  $\pm$  SD) non-smoker males participated in the study (Table 1). Trained participants cycled on average  $300 \pm 100$  km week<sup>-1</sup>, whereas untrained participants undertook no regular exercise.

### Experimental design

Participants were required to attend the laboratory on three separate occasions. The first visit involved a peak pulmonary oxygen consumption test during cycling ( $\dot{V}_{O_2\text{peak}}$ ), followed 2–3 days later by a 30 min familiarisation ride at a workload calculated from the

**Table 1. Subject characteristics**

Parameter	Untrained	Trained
Age (years)	23 $\pm$ 3	26 $\pm$ 2
Weight (kg)	69 $\pm$ 9	72 $\pm$ 4
Height (m)	1.75 $\pm$ 0.35	1.76 $\pm$ 0.39
BMI (kg m <sup>-2</sup> )	22 $\pm$ 2.6	23 $\pm$ 0.76
$\dot{V}_{O_2\text{peak}}$ (L min <sup>-1</sup> )	2.60 $\pm$ 0.4*	4.44 $\pm$ 0.35
$\dot{V}_{O_2\text{peak}}$ (ml kg <sup>-1</sup> min <sup>-1</sup> )	37.9 $\pm$ 5.6*	61.8 $\pm$ 2.2

Values are the mean  $\pm$  SD,  $n = 11$  untrained and 7 exercise trained participants, BMI, body mass index,  $\dot{V}_{O_2}$ , oxygen consumption. \*Significantly different to corresponding trained value ( $P < 0.05$ ).

$\dot{V}_{O_2\text{peak}}$  test to be  $\sim 65\%$   $\dot{V}_{O_2\text{peak}}$  to confirm the power output for the experimental trials. Approximately 1 week later, participants returned to the laboratory for an exercise trial, which involved cycling for 120 min at  $\sim 65\%$   $\dot{V}_{O_2\text{peak}}$  (untrained;  $100 \pm 21$  W; trained  $190 \pm 15$ ) (Table 2).

### Dietary and exercise controls

All participants were asked to refrain from any formal exercise for 48 h prior to the experimental trial to minimise any acute exercise training effects and to avoid drinking alcohol or consumption of caffeine for 24 h prior. To ensure the energy intake was controlled between groups, participants were supplied with a diet to consume over the 24 h prior to each experimental trial containing  $\sim 199$  kJ kg<sup>-1</sup> consisting of  $\sim 65\%$  of carbohydrates,  $\sim 15\%$  proteins and  $\sim 20\%$  fats. Participants were instructed to adhere to the diet but to consume water *ad libitum* and to finish the food by 10pm the evening prior to the experimental trial to enable attending the laboratory in a fasted state.

### Exercise trials

On the morning of the exercise trial, a 22 gauge Teflon catheter (Optiva; Ethicon Endo-Surgery, Cincinnati, OH, USA) was inserted into an antecubital forearm vein for blood sampling. The exercise protocol consisted of cycling for 120 min at 65% of  $\dot{V}_{O_2\text{peak}}$ . Blood was sampled 10 min prior to the commencement of exercise and then every 30 min during exercise for the measurement of plasma glucose, lactate, insulin, glycerol and free fatty acids. Expired air was collected into Douglas bags every 30 min during exercise and heart rate (Polar Favor, Oulu, Finland) was recorded every 30 min during exercise.  $\dot{V}_{O_2}$  and the respiratory exchange ratio were calculated from the expired air samples. Participants received 8 ml kg<sup>-1</sup> body weight of water at the start of exercise, followed by a further

2 ml kg<sup>-1</sup> body weight every 15 min of exercise and were fan cooled throughout the trial. At rest and after 30 and 120 min of exercise, muscle was obtained from the vastus lateralis under local anaesthesia, using the percutaneous needle biopsy technique, with suction. Muscle samples were rapidly (8–12 s from stopping exercise) frozen and stored in liquid N<sub>2</sub> for later analysis of AMPK  $\alpha 1$  and  $\alpha 2$  activity, AMPK  $\alpha$ Thr<sup>172</sup> phosphorylation and ACC $\beta$  Ser<sup>222</sup> phosphorylation and muscle metabolites.

### Analytical techniques

**Blood.** Plasma glucose, lactate (Lowry OH, 1972) and glycerol (Chernick, 1969) were determined using an enzymatic fluorometric procedure, plasma non-esterified fatty acids (NEFA) by an enzymatic colorimetric method (NEFA-C test, Wako, Osaka, Japan) and plasma insulin using a human insulin-specific radioimmunoassay kit (Linco Research, St Charles, MO, USA).

**Muscle metabolites.** A portion of each muscle sample (~20 mg) was freeze-dried and subsequently crushed to a powder and any visible connective tissue was removed. The extraction of muscle glycogen commenced by incubating the sample in HCl before being neutralized with NaOH and subsequently analysed for glucosyl units using an enzymatic fluorometric method (Passonneau & Lauderdale, 1974). The metabolites (ATP, CrP, Cr and lactate) were extracted firstly with precooled perchloric acid/EDTA before the addition of precooled KHCO<sub>3</sub> to the supernatant. The metabolites were analysed in triplicate using an enzymatic fluorometric method as reported by Harris *et al.* (1974). PCr, Cr and ATP were normalised to the participant's highest total creatine (Cr + CrP). The concentration of ADP (ADP<sub>free</sub>) and AMP (AMP<sub>free</sub>) was calculated based on the near equilibrium nature of the CK and adenylate kinase reactions, respectively. ADP<sub>free</sub> was calculated from the measured ATP, Cr, PCr levels and the estimated H<sup>+</sup> concentration, which was calculated from

a formula based on the muscle lactate content for dry muscle (Mannion *et al.* 1993). The observed equilibrium constant ( $K_{\text{obs}}$ ) of  $1.66 \times 10^9$  was used for creatine kinase (Lawson & Veech, 1979). An estimation of AMP<sub>free</sub> was calculated from the measured ATP and estimated ADP<sub>free</sub>, using a  $K_{\text{obs}}$  of 1.05 for adenylate kinase (Lawson & Veech, 1979). Estimated ADP<sub>free</sub> and AMP<sub>free</sub> were expressed as  $\mu\text{mol}$  per kilogram of dry muscle mass ( $\mu\text{mol kg}^{-1}$  dry muscle).

**Immunoblotting.** Frozen skeletal muscle was homogenised in ice cold lysis buffer on ice [10  $\mu\text{l mg}^{-1}$  tissue; 50 mM Tris-HCl, pH 7.5, containing 1 mM EDTA, 1 mM EGTA, 10% v/v glycerol, 1% v/v Triton X-100, 50 mM NaF, 5 mM Na<sub>4</sub>P<sub>2</sub>O<sub>7</sub>, 1 mM dithiothreitol, 1 mM phenylmethylsulphonyl fluoride, 1  $\mu\text{l ml}^{-1}$  trypsin inhibitor and 5  $\mu\text{l ml}^{-1}$  protease inhibitor cocktail (P8340; Sigma, St Louis, MO, USA)], incubated on ice for 20 min and centrifuged at 16 000 g for 20 min at 4°C. The protein concentration of samples was determined using the bicinchoninic acid protein assay (Pierce, Rockford, IL, USA) with BSA as the standard. All primary antibodies were diluted to a final concentration of 1:1000. Phosphospecific antibodies for AMPK  $\alpha$ Thr<sup>172</sup> and ACC $\beta$  Ser<sup>221</sup> were purchased from Upstate Biotechnology (Lake Placid, NY, USA; catalogue no. 07–626 and 05–673, respectively). Polyclonal rabbit antibody specific for total AMPK  $\alpha$  protein was purchased from Cell Signalling Technology (Beverly, MA, USA; catalogue no. 2532). ACC $\beta$  was detected using IRDye<sup>TM</sup> 800-labelled streptavidin (Rockland, Gilbertsville, PA, USA; catalogue no. S000-45).

Skeletal muscle lysates (80  $\mu\text{g}$ ) were heated in SDS sample buffer and subjected to SDS-PAGE. Binding of purified proteins was detected by immunoblotting following an overnight incubation with primary antibody. Membranes were incubated in Odyssey anti-rabbit IRDye<sup>TM</sup> 800- or anti-mouse IRDye<sup>TM</sup> 700- labelled secondary antibody (Rockland, Gilbertsville, PA, USA), washed in PBS Tween 20 and were scanned for infra-red fluorescence using an Odyssey Infrared Imaging System (LI-COR Biosciences, Lincoln, NE, USA). When both total protein and protein phosphorylation were measured, membranes were probed first for total protein, stripped of antibodies (2% SDS in 25 mM glycine, pH 2.0) and re-probed with the anti-phospho antibody. Phosphorylation was expressed relative to the total protein of the specific protein of interest.

**AMPK activity.** Skeletal muscle lysates (50  $\mu\text{g}$ ) were combined with 15  $\mu\text{l}$  of protein A sepharose beads (Pierce), bound to either AMPK  $\alpha 1$  (raised to the non-conserved region of the AMPK  $\alpha 1$  isoform, amino acid sequence 373–390 of rat AMPK  $\alpha 1$ ) or AMPK  $\alpha 2$  (amino acid

sequences 351–366 and 490–516 of rat AMPK $\alpha$ 2) polyclonal antibodies (a gift from Professor Bruce Kemp, St Vincent's Institute of Medical Research, Fitzroy, VIC, Australia) and incubated for 2 h at 4 °C. Immuno-complexes were washed in lysis buffer containing 0.5 M NaCl and resuspended in 25  $\mu$ l of 0.05 M Tris buffer (pH 7.5). To commence the assay, 25  $\mu$ l of reaction mixture containing (final concentrations) 50 mM Tris/HCl, pH 7.5, 0.1 mM EGTA, 0.1% (by vol) 2-mercaptoethanol, 10 mM magnesium acetate, 0.1 mM [<sup>32</sup>P]ATP (~200 cpm/pmol; PerkinElmer Life and Analytical Sciences, Boston, MA, USA), 30  $\mu$ M AMARA peptide (Upstate Biotechnology) and 200  $\mu$ M AMP was added to each sample at 30°C for 20 min with agitation. Then, 40  $\mu$ l of each sample was transferred onto P81 chromatography paper and washed 3 × 10 min in 75 mM H<sub>3</sub>PO<sub>4</sub>, once in 100% ethanol, and air dried. P81 paper was then placed in organic scintillation fluid (Opti-Fluor O; PerkinElmer) and radioactivity was counted on a  $\beta$  counter (PerkinElmer). AMARA peptide has the same AMPK phosphorylation site as ACC $\beta$ ; therefore, AMPK activities were calculated as units of  $\gamma$ -[<sup>32</sup>P]-ATP incorporated into the AMARA peptide [ACC $\alpha$  (73-87)A<sup>77</sup>] min<sup>-1</sup> mg<sup>-1</sup> total protein subjected to immunoprecipitation.

**Statistical analysis.** Data are expressed as the mean ± SD. Untrained and exercise trained group values were compared using a two-factor (training × time) repeated measures ANOVA and, if there was a significant interaction, the ANOVA was followed by a *post hoc* comparison

using a least significant difference test.  $P < 0.05$  was considered statistically significant.

## Results

### Subjects

There was no significant difference in age, weight, height or body mass index between the untrained and exercise trained groups (Table 1). However, as expected,  $\dot{V}_{O_2\text{peak}}$  was significantly higher in the endurance trained group ( $P < 0.05$ ) (Table 1) and the trained group cycled on average at almost twice the workload of the untrained group ( $P < 0.05$ ) (Table 2). Importantly, the relative exercise intensity was the same between groups, with no significant difference for  $\dot{V}_{O_2}$  (as a percentage of  $\dot{V}_{O_2\text{peak}}$ ), heart rate or rating of perceived exhaustion (Table 2).

### Muscle metabolites

Measured muscle lactate and Cr and estimated ADP<sub>free</sub>, AMP<sub>free</sub> and the AMP<sub>free</sub>:ATP ratio all increased progressively with exercise in both groups (Table 3). The exercise induced increase in muscle lactate, Cr and AMP<sub>free</sub> was attenuated in the exercise trained compared to the untrained group ( $P < 0.05$ ) (Table 3). Skeletal muscle AMP<sub>free</sub> increased ( $P < 0.05$ ) 17-fold in the untrained group and significantly ( $P < 0.05$ ) less (5-fold) in the endurance trained group following 120 min of exercise and the muscle lactate concentration increased by 5.9-fold in

the untrained and 3.1-fold in the well trained individuals ( $P < 0.05$ ) (Table 3). PCr and the PCr:(PCr+Cr) ratio decreased progressively in both groups, and this decrease was greater in untrained subjects (~26% decrease in untrained, ~44% decrease in endurance trained groups,  $P < 0.05$ ) (Table 3). There was no difference in measured ATP levels during exercise or between groups ( $P > 0.05$ ) (Table 3).

Resting muscle glycogen levels were 93% higher ( $P < 0.05$ ) in the exercise trained group, and remained higher than the untrained values at 30 min (130%,  $P < 0.05$ ) and 120 min of exercise (440%,  $P < 0.05$ ) (Fig. 1). However, net glycogen utilization during exercise was similar between the two groups.

### Plasma glucose lactate, insulin, glycerol and NEFA

Plasma glucose concentration remained at a similar level during exercise in untrained and endurance trained subjects ( $P > 0.05$ ) (Fig. 2A). Plasma lactate was similar at rest in the two groups; however, it was elevated by ~110% in the untrained group during exercise, which was significantly higher than the trained group ( $P < 0.05$ ) (Fig. 2B). Plasma insulin decreased progressively throughout exercise in both groups; however, fasting plasma insulin was 40% higher in the untrained compared to the trained group at rest, and remained ~25% higher than the trained values throughout 120 min of exercise ( $P < 0.05$ ) (Fig. 2C). Both plasma glycerol and NEFA increased progressively throughout exercise in both groups; however, NEFA levels were attenuated in the exercise trained group at 90 and 120 min ( $P < 0.05$ ) (Fig. 3).

**Figure 1. Muscle glycogen measurements in muscle samples**

Muscle glycogen measured from muscle samples obtained before exercise (rest), after 30 min and immediately following 120 min of steady-state exercise at ~65%  $\dot{V}_{O_{2peak}}$  in untrained and exercise trained participants. Data are the mean  $\pm$  SD ( $n = 11$  untrained, 7 trained). \*Significantly different to corresponding trained value ( $P < 0.05$ ). §Main effect for time ( $P < 0.05$ ).

### AMPK signalling

Basal AMPK  $\alpha 1$  activity was 90% higher ( $P < 0.05$ ) in the exercise trained group, whereas there was no difference in basal AMPK  $\alpha 2$  activity between the two groups (Fig. 4). AMPK  $\alpha 1$  activity increased by 220% and AMPK  $\alpha 2$  activity increased by 370% during exercise in the untrained

**Figure 2. Plasma glucose, lactate and insulin concentrations**

Plasma glucose (A), plasma lactate (B) and plasma insulin (C) concentrations at rest and during 120 min of steady-state exercise at ~65%  $\dot{V}_{O_{2peak}}$  in untrained and exercise trained participants. Data are the mean  $\pm$  SD,  $n = 11$  untrained, 7 trained. \*Significantly different from corresponding trained value ( $P < 0.05$ ).

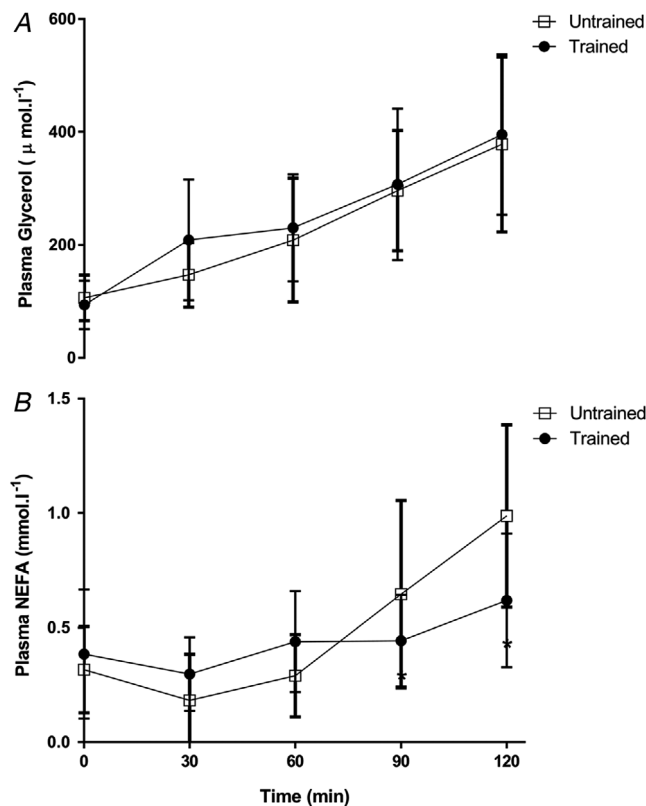

group at 120 min ( $P < 0.05$ ). However, neither AMPK  $\alpha 1$ , nor AMPK  $\alpha 2$  activity increased during exercise in the endurance trained group ( $P > 0.05$ ) (Fig. 4). AMPK  $\alpha$ Thr<sup>172</sup> (115%,  $P < 0.05$ ) phosphorylation and ACC $\beta$  Ser<sup>222</sup> phosphorylation (100%,  $P < 0.05$ ) increased with exercise in the untrained group after 120 min of exercise (Fig. 5). However, there was no significant increase in AMPK  $\alpha$ Thr<sup>172</sup> phosphorylation or ACC $\beta$  Ser<sup>222</sup> phosphorylation during exercise in the trained group ( $P > 0.05$ ) (Fig. 5).

## Discussion

The results of the present study show that AMPK activity is not increased during prolonged steady-state, moderate intensity exercise in endurance trained individuals. Indeed, AMPK  $\alpha 1$  and  $\alpha 2$  activity was significantly elevated following 120 min of exercise in the untrained group (220% and 370%, respectively), whereas no increase in AMPK activity was observed during exercise in the trained participants (Fig. 4). Given that there is a substantial amount of glucose and fat oxidised during 120 min

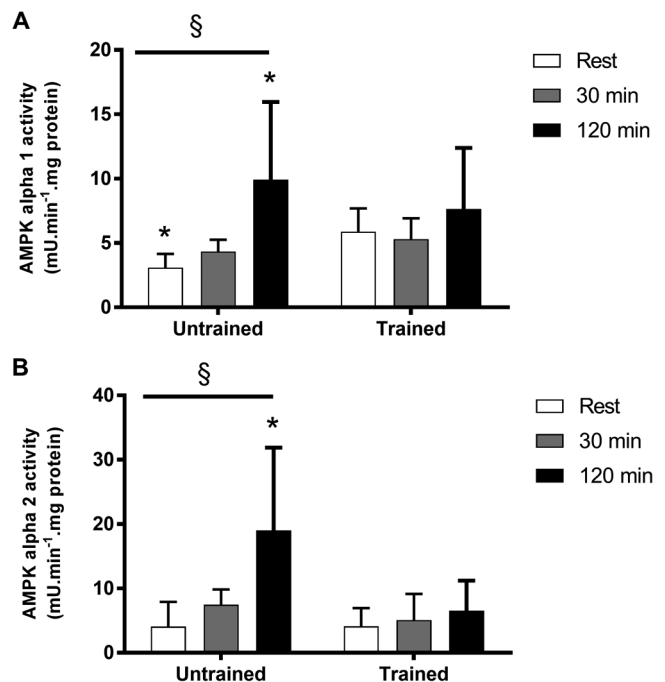

of exercise at 65%  $\dot{V}_{O_{2peak}}$  in endurance trained individuals (Romijn *et al.* 1993; van Loon *et al.* 2001), these results indicate that AMPK activation is not important for exercise metabolism under these circumstances.

Almost every study investigating AMPK states in their Introduction that AMPK regulates glucose uptake and fat oxidation during exercise, despite much evidence to the contrary. Indeed, our current findings are consistent with our previous results indicating that, after 10 days of exercise training, there was no increase from rest in skeletal muscle AMPK activity, AMPK  $\alpha$ Thr<sup>172</sup> phosphorylation or ACC $\beta$  phosphorylation during 120 min of exercise at 65% of pre-training  $\dot{V}_{O_{2peak}}$  despite substantial glucose disposal and higher fat oxidation during exercise after (compared to before) exercise training (McConnell *et al.* 2005). Other studies similarly report in humans that skeletal muscle AMPK activation is barely increased during exercise at 65%  $\dot{V}_{O_{2peak}}$  after 12 weeks of exercise training (Mortensen *et al.* 2013). Although not universally the case (Mu *et al.* 2001; Sakamoto *et al.* 2005; Lee-Young *et al.* 2009), many rodent studies have found that there are normal increases in glucose uptake and fat oxidation during contraction or during exercise in AMPK kinase dead or AMPK knockout mice (Jorgensen *et al.* 2004;

**Figure 3. Plasma glycerol and nonesterified fatty acid concentrations**

Plasma glycerol (A) and plasma nonesterified fatty acid (NEFA) (B) concentrations at rest and during 120 min of steady-state exercise at  $\sim 65\%$   $\dot{V}_{O_{2peak}}$  in untrained and exercise trained participants. Data are the mean  $\pm$  SD,  $n = 11$  untrained, 7 trained.

**Figure 4. Skeletal muscle AMPK  $\alpha 1$  and  $\alpha 2$  activity**

AMPK  $\alpha 1$  (A) and  $\alpha 2$  activity (B). Muscle samples were obtained before exercise (rest), after 30 min and immediately following 120 min of steady-state exercise at  $\sim 65\%$   $\dot{V}_{O_{2peak}}$  in untrained and exercise trained participants. Data are the mean  $\pm$  SD,  $n = 11$  untrained, 7 trained. \*Significantly different from corresponding trained value ( $P < 0.05$ ). §Main effect for time ( $P < 0.05$ ).

Fujii *et al.* 2005; Merry *et al.* 2010b; Jeppesen *et al.* 2011; Jeppesen *et al.* 2013; Kjobsted *et al.* 2017).

Unlike the present study, it was reported previously that skeletal muscle AMPK activity increases similarly in untrained and well trained people cycling for 20 min at 80%  $\dot{V}_{O_{2peak}}$  (Nielsen *et al.* 2003). In addition, Clark *et al.* (2004) found AMPK activity increased similarly during repeated bouts of exercise at 85%  $\dot{V}_{O_{2peak}}$  after exercise training despite evidence of lower energy deficit after the exercise training. In the present study, exercise was performed at  $\sim 65\%$  of  $\dot{V}_{O_{2peak}}$  (untrained 66%; trained 65%) (Table 2); some may argue that this workload is quite easy for trained individuals and so no increase in AMPK activation would be expected. However, because there are 2–3-fold increases from rest in whole-body glucose uptake and fat oxidation during moderate intensity exercise at  $\sim 65\%$   $\dot{V}_{O_{2peak}}$  in endurance trained individuals (Romijn *et al.* 1993; van Loon *et al.* 2001), factors that are important to mediating exercise metabolism should be enhanced at these workloads. Therefore, activation

of skeletal muscle AMPK is probably not necessary for increases in glucose uptake and fat oxidation during moderate intensity exercise in humans. These findings are also supported by other human studies that found dissociations between AMPK activation and glucose uptake and fat oxidation during prolonged exercise at 40–45%  $\dot{V}_{O_{2max}}$  (Chen *et al.* 2000; Wojtaszewski *et al.* 2002).

AMPK activity is increased by upstream kinase phosphorylation and allosterically by increases in AMP (Hardie, 2004; Sakamoto *et al.* 2005). In addition, ADP increases AMPK activity by preventing dephosphorylation of AMPK (Xiao *et al.* 2011). Exercise increases skeletal muscle free ADP and AMP (McConell *et al.* 1999) and exercise training attenuates the normal increases in ADP and AMP during exercise compared to untrained muscle (Gollnick & Hermansen, 1973). Indeed, in the present study, we report an attenuated increase in calculated AMP and ADP during exercise in the well trained compared to the untrained participants (Table 3) and thus would

**Figure 5. Skeletal muscle AMPK  $\alpha$ Thr<sup>172</sup> and ACC- $\beta$ Ser<sup>221</sup> phosphorylation**

Representative immunoblot of AMPK  $\alpha$ Thr<sup>172</sup> phosphorylation (A) measured using a phosphospecific antibody for AMPK  $\alpha$ Thr<sup>172</sup>, normalized to total AMPK  $\alpha$  protein; and ACC- $\beta$ Ser<sup>221</sup> phosphorylation (B) measured using a phosphospecific antibody specific to ACC- $\beta$ Ser<sup>221</sup>, normalized to total ACC- $\beta$ . Muscle samples were obtained before exercise (rest), after 30 min and immediately following 120 min of steady-state exercise at  $\sim 65\%$   $\dot{V}_{O_{2peak}}$  in untrained and exercise trained participants. Samples of pAMPK or AMPK for each participant were run on the same western blot. The representative western blots for pAMPK or AMPK shown are from the same membrane but are rearranged for clarity. Data are the mean  $\pm$  SD,  $n = 11$  untrained, 7 trained. \*Significantly different from corresponding trained value ( $P < 0.05$ ). §Main effect for time ( $P < 0.05$ ).

have expected a similar attenuated response in AMPK activity. In the present study, despite the five-fold increase in AMP<sub>free</sub> during exercise in the trained individuals AMPK activity was not increased from rest. Future studies should investigate whether there is a reduction in AMPK sensitivity to AMP and ADP during moderate intensity exercise after exercise training. This could be carried out in highly trained endurance subjects by using exercise intensity to titrate the free AMP levels to compare the threshold for AMPK activation during exercise in endurance trained vs. untrained individuals.

It is possible that AMPK activation during exercise in the trained individuals was restrained by the higher muscle glycogen since muscle glycogen content has also been implicated as a potential regulator of AMPK activation during exercise. Indeed, the  $\beta$  subunit contains a glycogen binding domain that associates with glycogen in cell free assays (Hudson *et al.* 2003; Polekhina *et al.* 2003). High muscle glycogen has been shown to inhibit contraction induced AMPK activation without influencing glucose uptake in rats (Derave *et al.* 2000). However, there is evidence to suggest that AMPK does not associate with glycogen *in vivo* (Viollet *et al.* 2003; Parker *et al.* 2007). Indeed our laboratory has shown that muscle glycogen is not responsible for abolished AMPK activity during exercise in humans. Following short-term exercise training, there is no increase in AMPK activity during exercise commenced with normal or high glycogen levels (McConell *et al.* 2005). In the present study, muscle glycogen content was 93% higher in the trained subjects at rest, and remained higher than untrained values throughout the exercise trial (Fig. 1). However, given the findings of our short-term exercise training study (McConell *et al.* 2005), as well as other evidence of a lack of importance of AMPK for *in vivo* muscle glycogen content (Viollet *et al.* 2003), the higher muscle glycogen content in the endurance trained individuals was probably not responsible for the abolished increase in AMPK activity during exercise.

It is not clear why activation of AMPK  $\alpha$ Thr<sup>172</sup> phosphorylation and AMPK activity did not occur during exercise in the exercise trained individuals; however, there is some evidence to suggest that training is associated with changes in the regulation of upstream AMPKK(s). For example, endurance training in rats decreases basal LKB1 activity (Hurst *et al.* 2005) and decreases AMPK activity during exercise (Durante *et al.* 2002). It is also not known what effect exercise training has on PP2C activity, and it may be that increases in PP2C activity following training are preventing AMPK  $\alpha$ Thr<sup>172</sup> phosphorylation and increases in AMPK activity during exercise. PP2C has previously been shown to inhibit the activity of both AMPK  $\alpha$ 1 and  $\alpha$ 2 isoforms (Davies *et al.* 1995); however, further studies are required to determine whether changes in PP2C activity occur following exercise training.

In summary, the present study found that, unlike untrained individuals, endurance trained men have no increase in skeletal muscle AMPK activity, AMPK phosphorylation or ACC phosphorylation during 120 min of cycling exercise at  $\sim 65\%$   $\dot{V}_{O_{2peak}}$ . This finding is consistent with results following short-term exercise training where no increase in AMPK activation during moderate intensity exercise is also observed (McConell *et al.* 2005). Given that skeletal muscle AMPK is not activated but fat oxidation and glucose uptake are substantial during moderate intensity exercise after exercise training, these results indicate that AMPK does not regulate metabolism under these circumstances.
